Title: Generating random pattern-avoiding matrices

Author: Stanislav Kučera

Department: Computer Science Institute of Charles University

Supervisor: RNDr. Vít Jelínek, Ph.D., department

Abstract: Binary matrices not containing a smaller matrix as a submatrix became an interesting topic recently. In my thesis, I introduce two new algorithms to test whether a big square binary matrix contains a smaller binary matrix together with a process using randomness, which approximates a uniformly random matrix not containing a given matrix. The reason to create such algorithms is to allow researchers test their conjectures on random matrices. Thus, my thesis also contains an effective cross-platform implementation of all mentioned algorithms.

Keywords: binary matrix pattern-avoiding Markov chain Monte Carlo

I would like to thank my supervisor, Vít Jelínek, for his patience and willingness to spend so much time helping me improve the thesis. I also thank to Paul Macklin, author of EasyBMP (<http://easybmp.sourceforge.net/>) – a library for working with bmp files, which I use in my program.

# 1 Preface

2 Theses at the Faculty of Mathematics and Physics of Charles University in Prague  
3 usually fit into one of three categories:

- 4     1. Theoretical thesis
- 5     2. Experimental thesis
- 6     3. Implementation thesis

7 My thesis does not fit entirely into only one category and it does not try to. The  
8 project consists of several similarly important parts which are:

- 9       • Design of algorithms for generating a special binary matrix
- 10      • Making the algorithms run fast on inputs that are usual for researchers
- 11      • Implementation of the algorithms to provide a practical tool

12 One part would not make sense without others, but together, the thesis may  
13 become a very useful tool for scientists interested in matrices with forbidden  
14 patterns as the thesis provides them with a process of generating random pattern-  
15 avoiding matrices.

# Introduction

Throughout the thesis, we will be concerned with binary matrices and something called *pattern*, which will also be a binary matrix.

**Definition 1.** We let  $M \in \{0, 1\}^{m \times n}$  denote a *binary matrix* of size  $m$  by  $n$ . The *height* of  $M$ , denoted by  $m$ , is the number of rows of  $M$  and  $n$  is its width (the number of columns).

**Definition 2.** A *line* of a matrix is one of its rows or columns and we denote by  $L(M)$  the ordered set of all lines of  $M$ . Its order is given by the standard indexing of rows and columns.

**Definition 3.** We say a binary matrix  $M$  *contains* a binary matrix  $P$ , which we call a pattern, as a submatrix, if there is a mapping  $f : L(P) \rightarrow L(M)$ , such that

- $l \in L(P)$  is a row of  $P$  if and only if  $f(l) \in L(M)$  is a row of  $M$
- $\forall l, l' \in L(P) : l < l' \Rightarrow f(l) < f(l')$  (preserves the order)
- $\forall l, l' \in L(P) : \text{if lines } l \text{ and } l' \text{ intersect and there is a one-entry at the intersection, then there is a one-entry at the intersection of } f(l) \text{ and } f(l').$

otherwise, it *avoids* the pattern  $P$ .

$$P = \begin{matrix} & \begin{matrix} 2 & 3 \end{matrix} \\ \begin{matrix} 0 \\ 1 \end{matrix} & \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \end{matrix} \quad M_1 = \begin{matrix} & \begin{matrix} 3 & 4 & 5 \end{matrix} \\ \begin{matrix} 0 \\ 1 \\ 2 \end{matrix} & \begin{pmatrix} 1 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix} \end{matrix} \quad M_2 = \begin{matrix} & \begin{matrix} 3 & 4 & 5 \end{matrix} \\ \begin{matrix} 0 \\ 1 \\ 2 \end{matrix} & \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix} \end{matrix}$$

Figure 1: Matrix  $M_1$  contains the pattern  $P$ , because all the conditions are satisfied by mapping  $\{(0, 0), (1, 2), (2, 3), (3, 4)\}$ . On the other hand, matrix  $M_2$  avoids  $P$  as there is no such mapping.

The interesting cases are square matrices of size  $n$  by  $n$ , where  $n$  is big (going to infinity) and the size of a pattern (not necessarily square matrix) is small (constant). Even for a constant size forbidden pattern it is hard to determine the number of matrices of size  $n$  that avoid it or to characterize, what properties they have. That is why it is useful to have a tool generating random matrices. Sometimes we consider matrices avoiding more than just one forbidden pattern, in which case we denote the set of all forbidden matrices by  $\mathcal{P}$ . When a matrix avoids  $\mathcal{P}$ , it avoids every  $P \in \mathcal{P}$ .

**Notation 1.** We denote by  $\mathcal{M}_n(\mathcal{P})$  a set of all binary matrices of size  $n$  by  $n$  avoiding  $\mathcal{P}$  as submatrices.

**Notation 2.** We always call  $M$  the square binary matrix, for which we test the containing, and  $P$  the pattern (if there is only one) that is being tested. Moreover, we denote by  $h$  the height (the number of rows) of  $P$  and by  $w$  its width.

45 The area of pattern avoidance has been heavily studied for permutations and  
 46 it also becomes more popular for their generalization – binary matrices. In most  
 47 of the areas in combinatorics, it is useful to explore properties of random objects  
 48 and a lot of attention is directed towards random matrices when considering  
 49 pattern avoidance. The goal of the thesis is, for given  $n \in \mathbb{N}$  and set of forbidden  
 patterns  $\mathcal{P}$ , to generate a uniformly random  $M \in_R \mathcal{M}_n(\mathcal{P})$ .

Figure 2: Example of a generated matrix avoiding  $I_{10}$  (unit matrix). Black dots are one-entries and white are zero-entries. As you can see, matrices avoiding a pattern can have a nice structure.

50

## 51 Generating random matrices

52 One way to get  $M \in_R \mathcal{M}_n(\mathcal{P})$  is to choose a matrix of required size completely  
 53 at random, for such, test whether it avoids the pattern and simply repeat the  
 54 process until we find one, which does. However, in the most interesting cases,  
 55 only a small fraction of all matrices avoid the pattern and the process takes too  
 56 long, to be practically useful.

57 For generating random permutations avoiding forbidden pattern, a different  
 58 technique was introduced in Madras and Liu [2010]. It uses a randomized pro-  
 59 cess called Markov chain Monte Carlo, which we will abbreviate by MCMC. It  
 60 is an iterative process, which for a well chosen Markov chain (more in Chapter  
 61 1) approximates a random object. The algorithm by Madras and Liu was devel-  
 62 oped for permutations (permutation matrices) and it cannot be used for general  
 63 matrices. In Section 1.2 we show how to adapt the algorithm, which will lead  
 64 us to a MCMC algorithm that approximates  $M \in_R \mathcal{M}_n(\mathcal{P})$ . To produce a good  
 65 approximation the process needs to do a lot of iterations and despite the fact  
 66 it is unknown what is the mixing time (the number of iterations required) of a  
 67 MCMC process, in practice, the method does better than the trivial algorithm.

## 68 Testing avoidance

69 In each step of our MCMC process, we need to test whether a matrix avoids a  
 70 pattern. We will show a very fast algorithm that only works for a special class of  
 71 binary matrices (explained in Chapter 3) together with a slightly less performing

72 algorithm for a general pattern, which, again, comes as a generalization of an  
73 algorithm for permutations from the article by Madras and Liu and is described  
74 in Chapter 2.

75 In Chapter 4, we improve both our algorithms and introduce a parallel version  
76 of MCMC process, which further increases the performance of matrix generating.

77 Some technical details are explained in Chapter 5 to make reading the code  
78 easier for reader. The last chapter (Chapter 6) contains user documentation.

# 1. Markov chain Monte Carlo

Our goal to generate  $M \in_R \mathcal{M}(\mathcal{P})$  heavily depends on the theory of Markov chains. We only define useful terms and state two important theorems. If you are interested in more details, see Madras [2002].

## 1.1 Markov chains

**Definition 4.** Let  $\mathcal{S}$  be a finite set of states and for every  $i, j \in \mathcal{S}$   $p_{i,j}$  prescribed probability of a change of state from  $i$  to  $j$ . Also let  $X_0$  be a random variable with values from  $\mathcal{S}$ . We call a sequence  $X_0, X_1, \dots$ , where  $X_i \in \mathcal{S}$  for every  $i$  a *Markov chain* if

$$Pr(X_{t+1} = j | X_t = i) = p_{i,j} \quad (i, j \in \mathcal{S})$$

**Definition 5.** A Markov chain is said to be *symmetric* if  $p_{i,j} = p_{j,i}$  for every pair of states  $i$  and  $j$ .

**Definition 6.** A Markov chain is *irreducible* if the chain can eventually get from each state to every other state, that is, for every  $i, j \in \mathcal{S}$  there exists a  $k \geq 0$  (depending on  $i$  and  $j$ ) such that  $Pr(X_k = j | X_0 = i) > 0$ .

**Definition 7.** If an irreducible chain has  $p_{i,i} > 0$  for some  $i$ , then it is *aperiodic*.

Let  $p_{i,j}^{(k)} = Pr(X_{t+k} = j | X_t = i)$  denote the  $k$ -step transition probabilities for  $k = 0, 1, \dots$  and  $i, j \in \mathcal{S}$ . The transition probability matrix is  $P = (p_{i,j})$ .

Next we state two theorems allowing us to expect Markov chains to converge to a uniformly random state in  $\mathcal{S}$  even if the initial state  $X_0$  is not random. Both theorems can be found in Madras [2002].

**Theorem 1.** Consider an aperiodic irreducible Markov chain with finite state space  $\mathcal{S}$ . For every  $i, j \in \mathcal{S}$ , the limit  $\lim_{k \rightarrow \infty} p_{i,j}^{(k)}$  exists and is independent of  $i$ ; call it  $\pi_j$ . Furthermore,

$$\sum_{j \in \mathcal{S}} \pi_j = 1 \quad \wedge \quad \sum_{i \in \mathcal{S}} \pi_i p_{i,j}^{(1)} = \pi_j$$

for every  $j \in \mathcal{S}$ .

**Theorem 2.** Suppose that an irreducible Markov chain on the finite state space  $\mathcal{S}$  is symmetric. Then the equilibrium distribution is uniform on  $\mathcal{S}$ .

## 1.2 Markov chain for pattern-avoiding binary matrices

To generate a binary matrix  $M \in \{0, 1\}^{n \times n}$  avoiding patterns in  $\mathcal{P}$ , we create a Markov chain, whose states space is  $\mathcal{M}_n(\mathcal{P})$ . After sufficiently many iterations ( $m$ ) of MCMC process we set  $M := X_m \in \mathcal{M}_n(\mathcal{P})$ . We always begin with an initial matrix  $X_0$  and the process looks like this:

- 104 1. For  $i := 1, 2, \dots, m$ :
- 105 2. Set  $X_i := X_{i-1}$ .
- 106 3. Choose  $r \in_R \{0, 1, \dots, n-1\}$  uniformly at random.
- 107 4. Choose  $c \in_R \{0, 1, \dots, n-1\}$  uniformly at random.
- 108 5. Flip the bit at  $X_i[r, c]$ .
- 109 6. If  $X_i$  contains  $\mathcal{P}$ , flip the bit back.

110 If the process starts with a matrix  $X_0$  that avoids  $\mathcal{P}$ , then after every step it  
 111 still avoids  $\mathcal{P}$ . Note that an iteration does not change the matrix if the condition  
 112 6 is satisfied. We need to show the Markov chain we presented meets all the  
 113 conditions of both theorems:

### 114 Symmetry

115 Imagine a sequence of bits flipping that changes the  $i$ -th matrix to the  $j$ -th one.  
 116 The reversed order of the same sequence changes the  $j$ -th matrix to the  $i$ -th one.

### 117 Irreducibility

118 As the steps go, it is easy to see we can with non-zero probability create any  
 119 matrix  $M_1 \in \mathcal{M}_n(\mathcal{P})$  from the zero matrix  $0_n = 0^{n \times n}$  by choosing the one-entries  
 120 of  $M_1$ . When we can get from  $0_n$  to  $M_2$  by a sequence of flip changes, the reversed  
 121 sequence is a sequence of steps from  $M_2 \in \mathcal{M}_n(\mathcal{P})$  to  $0_n$ . Thus, with non-zero  
 122 probability we can always reach  $M_2$  from  $M_1$ ; therefore, the Markov chain is  
 123 irreducible.

### 124 Aperiodicity

125 The Markov chain is irreducible so it suffices to show that there is an  $i$  for which  
 126  $p_{i,i} > 0$ . Clearly, there is a matrix for which there is at least one bit that cannot  
 127 be flipped without creating a pattern (for example the one with the maximum  
 128 number of one-entries) and this forces  $p_{i,i} > 0$ .

## 129 2. An algorithm for testing 130 pattern-avoidance of a general 131 pattern

132 In this chapter and Chapter 3 we show algorithms for testing whether a pattern  
133  $P$  is contained in a square binary matrix  $M$ .

134 We begin with a very basic algorithm, which we then improve a lot to get a  
135 fast algorithm for testing the avoidance of a general pattern.

### 136 2.1 Sketch of a brute force algorithm

137 Let  $L = (l_1, l_2, \dots, l_{w+h})$  be a permutation of lines (rows and columns) of the  
138 pattern  $P$  and  $k \in [w+h]$ . *Partial mapping of level  $k$*  of lines of  $P$  is a function  
139  $f$  from  $L' := \{l_1, l_2, \dots, l_k\} \subseteq L$  to lines of the big matrix  $M$  satisfying three  
140 conditions:

- 141 • Both  $l' \in L'$  and  $f(l')$  are rows or they are both columns.
- 142 • If  $l' \in L'$  and  $l'' \in L'$  are both rows or columns and  $l' < l''$ , then  $f(l') < f(l'')$ .  
143 This means partial mapping keeps the order of the lines.
- 144 • If  $l' \in L'$  is a row of  $P$  and  $l'' \in L'$  is a column of  $P$  and there is a one-entry  
145 at the intersection of  $l'$  and  $l''$ , then there is a one-entry at the intersection  
146 of  $f(l')$  and  $f(l'')$ .

147 The basic algorithm we use goes as follows. First it maps  $l_1$  to all possible lines  
148 of  $M$ , creating partial mappings of  $\{l_1\} \subseteq L$ . For  $k = 2, \dots, w+h$  it takes each  
149 partial mapping from the previous iteration and extends it by adding line  $l_k$  to  
150 the partial mapping in all possible ways. If we manage to map all the lines of  $P$ ,  
151 then  $M$  does not avoid it and if at some point there are no partial mappings to  
152 extend it means  $M$  avoids  $P$ .

153 The algorithm can be improved in two ways. Firstly, we can try to recognize  
154 unextendable partial mappings earlier than at the moment a line can no longer be  
155 mapped, for example by counting whether there is enough one-entries in between  
156 already mapped lines (more in Section 4.1.5). Secondly, which is going to be  
157 fundamental for us, we can try not to remember more copies of different mappings  
158 that can be extended in the same way.

### 159 2.2 Equivalent mappings

160 There is no need to remember two different partial mappings of the same level  
161 if they can be both extended exactly the same way, because our function is only  
162 supposed to check whether a pattern can be mapped to a big matrix not to find  
163 all such mappings.

164 **Definition 8.** We call a line  $l$  of a pattern  $P$  *important* for chosen permutation  
165 of lines of  $P$ , if one of the conditions is met:

- An adjacent line of the pattern has not been mapped yet.
  - There is a one-entry on the line  $l$  at the intersection with line  $l'$  that has not been mapped yet.
- . Otherwise the line is *unimportant* for the permutation.

Whether a line is important or not only depends on the permutation, so if we have a line unimportant in a partial mapping of level  $k$ , it is unimportant in every partial mapping of level  $k$ .

At the beginning, when no line is mapped, all lines are important. After some lines get mapped, a line can become unimportant in the partial mapping as all lines that bound it are in the mapping as well. If a line is unimportant in a partial mapping of some level, it will stay unimportant in all extensions of the mapping we can find.

**Definition 9.** We say two partial mappings of the same level are *equivalent* if all important lines in the mapping of that level are mapped to the same lines of the big matrix in both mappings.

$$P = \begin{matrix} & 4 & 5 & 6 & 7 \\ \begin{matrix} 0 \\ 1 \\ 2 \\ 3 \end{matrix} & \begin{pmatrix} 1 & 1 & 0 & 0 \\ 0 & 1 & 1 & 1 \\ 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 \end{pmatrix} \end{matrix} \quad M = \begin{matrix} & 5 & 6 & 7 & 8 & 9 \\ \begin{matrix} 0 \\ 1 \\ 2 \\ 3 \\ 4 \end{matrix} & \begin{pmatrix} 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 0 & 1 \\ 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 \\ 1 & 1 & 1 & 0 & 1 \end{pmatrix} \end{matrix}$$

Figure 2.1: An example showing unimportant line and equivalent mappings.

For  $P$  and  $M$ , binary matrices in Figure 2.1, in partial mapping of level 4  $f = \{(1, 1), (2, 2), (3, 4), (5, 6)\}$ , line 2 is unimportant because both lines 1 and 3 are mapped and so is line 5 - the only line to intersect line 2 in a one-entry. Line 3 is important, because there is line 7 intersecting it in one-entry, which is not mapped.

In the same situation as above, consider a different partial mapping  $f' = \{(1, 1), (2, 3), (3, 4), (5, 6)\}$ , which is a mapping of the same level as  $f$  and only differs from  $f$  in mapping line 2. The line 2 is unimportant and by the definition of equivalent partial mappings,  $f$  and  $f'$  are equivalent. The idea behind this notion is simple. It is not important where we map line 2, because it does not restrict where we can map any other line that has not been mapped yet. This means that if a partial mapping  $f$  can be somehow extended, the equivalent partial mapping  $f'$  can be extended in the same way; therefore, it is sufficient to only extend one of them in order to find one full mapping. Note that it would be also sufficient to only extend one of the partial mappings if we were looking for all full mappings, but, in that case, we would need to keep the information about where the unimportant lines were mapped to.

# 3. An algorithm for testing pattern-avoidance of a special pattern

In the previous chapter, we have seen an algorithm for a general forbidden pattern. In this chapter, we introduce a special kind of a pattern, satisfying additional conditions, for which we can produce a much faster algorithm.

## 3.1 Walking pattern

**Definition 10.** A *walk* in a matrix  $P$  is a sequence of some of its entries, beginning in the top left corner and ending in the bottom right one. If an entry at the position  $[i, j]$  is in the sequence, the next one is either  $[i + 1, j]$  or  $[i, j + 1]$ . Let  $w$  denote the width of  $P$  and  $h$  denote its height, the length of an arbitrary walk is equal to  $w + h - 1$  and we denote elements of the sequence by  $w_1, w_2, \dots, w_{w+h-1}$ .

**Definition 11.** We call a binary matrix  $P$  a *walking pattern* if there is a walk in  $P$  such that all the one-entries of  $P$  are contained on the walk.

Figure 3.1: An example of a walk  $W$  in matrix  $M$  and the order of entries in  $W$ .

In Figure 3.1 matrix  $M$  is a walking pattern as all the one-entries are included in a walk. We can also see that not all entries of a walk need to be one-entries.

It can be shown a walking pattern is exactly a matrix avoiding a forbidden pattern  $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ .

## 3.2 Dynamic program

Next, we show an algorithm deciding whether a walking pattern  $P$  is contained in a big matrix  $M$  or not.

The pattern  $P$  is a walking pattern, so there is a walk containing all the one-entries of  $P$ . We choose one such walk arbitrarily. For each entry of the walk we remember whether its value in  $P$  is one or zero and whether the walk continues from the entry vertically, in which case we call it a *vertical entry* or horizontally, calling it a *horizontal entry*.

**Definition 12.** For an element  $e$  of  $M$  at the position  $[i, j]$ , the matrix  $M_{\leq e}$  is a  $(i+1) \times (j+1)$  submatrix of  $M$  consisting of rows with the index smaller than or equal to  $i$  and columns with the index smaller than or equal to  $j$ . The element  $e$  then lies in the bottom right corner. Similarly,  $M_{\geq e}$  is a  $(n-i) \times (n-j)$  submatrix of  $M$  consisting of rows with the index greater than or equal to  $i$  and columns with index greater than or equal to  $j$ . The element  $e$  is its first element.

To determine whether  $P$  is contained in  $M$  we find out for each element  $e$  of  $M$  what is the biggest index  $k$  such that there exists a mapping of  $P_{\leq w_k}$  to  $M_{\leq e}$ . If there is an element for which we manage to find the whole pattern ( $k = w + h - 1$ ),  $P$  is contained in  $M$ ; otherwise, it is avoided.

### 3.2.1 Inner structures

The algorithm uses two structures. For each  $w_k$  we remember whether it is a one-entry or zero-entry in  $P$  and whether it is a vertical entry or horizontal entry.

The second structure is a matrix of the same size as  $M$ . For each element  $e$  at the position  $[i, j]$  we store two numbers. The number  $c_v(e)$  is the biggest index  $k$  such that  $w_k$  is a vertical entry and there is a mapping of  $P_{\leq w_k}$  to  $M_{\leq e}$ , in which  $w_k$  is being mapped to the  $j$ -th column. The number  $c_h(e)$ , symmetrically, is the biggest index  $k$  such that  $w_k$  is a horizontal entry and there is a mapping of  $P_{\leq w_k}$  to  $M_{\leq e}$ , in which  $w_k$  is being mapped to the  $i$ -th row.

### 3.2.2 The algorithm

**Definition 13.** A *diagonal* of the matrix  $M$  is a subset of elements of  $M$ , such that all elements have the same sum of their coordinates.

For example, the zero diagonal only consists of the element  $[0, 0]$ , the first diagonal contains elements  $[0, 1]$  and  $[1, 0]$ , and so on.

Figure 3.2: Diagonals of an matrix and the order in which the algorithm for walking pattern iterates through them.

The algorithm iterates through diagonals. For simplicity, in the pseudo-code below we do not deal with elements outside  $M$  (like  $[-1, 0]$ ) explicitly. Instead, for those elements, we assume the values of  $c_v$  and  $c_h$  are always equal to zero and

251  $[-1, i]$  is a vertical entries and  $[i, -1]$  is a horizontal for every  $i \geq 0$ . When we ask  
 252 whether  $w_k$  can be mapped to  $e$ , where  $e$  is an element of  $M$ , we check whether  
 253  $w_k$  stands for a one-entry of  $P$  and if it does, we require  $e$  to be a one-entry too.  
 254 For an  $n \times n$  matrix  $M$  the algorithm works as follows:

- 255 1. For  $d = 0, \dots, 2n - 2$
- 256 2. For  $e$  element of  $d$ -th diagonal at the position  $[i, j]$
- 257 3.  $e_v := [i - 1, j]$
- 258 4.  $e_h := [i, j - 1]$
- 259 5.  $c_v(e) := c_v(e_v)$
- 260 6.  $c_h(e) := c_h(e_h)$
- 261 7. If  $w_{c_v(e_v)+1}$  can be mapped to  $e$
- 262 8. If  $c_v(e_v) + 1 = w + h - 1$
- 263 9. Terminate -  $M$  contains  $P$  as a submatrix
- 264 10. If  $w_{c_v(e_v)+1}$  is a vertical entry
- 265 11.  $c_v(e) := c_v(e_v) + 1$
- 266 12. Else
- 267 13.  $c_h(e) := \max\{c_h(e), c_v(e_v) + 1\}$
- 268 14. If  $w_{c_h(e_h)+1}$  can be mapped to  $e$
- 269 15. If  $c_h(e_h) + 1 = w + h - 1$
- 270 16. Terminate -  $M$  contains  $P$  as a submatrix
- 271 17. If  $w_{c_h(e_h)+1}$  is a vertical entry
- 272 18.  $c_v(e) := \max\{c_v(e), c_h(e_h) + 1\}$
- 273 19. Else
- 274 20.  $c_h(e) := \max\{c_h(e), c_h(e_h) + 1\}$

### 275 3.2.3 Correctness

276 The first observation we make is that for every element  $e$  of  $M$  and any element  
 277  $e'$  above  $e$  in the same column  $c_v(e') \leq c_v(e)$ . This holds because whenever  
 278 we manage to map  $P_{\leq w_k}$  to  $M_{\leq e'}$ , then the same mapping maps  $P_{\leq w_k}$  to  $M_{\leq e}$ .  
 279 Similarly, it also holds for every  $e$  element of  $M$  and any element  $e'$  to the left of  
 280  $e$  in the same row that  $c_h(e') \leq c_h(e)$ .

281 The function can terminate before recomputing all elements and we have no  
 282 guarantee about the state of elements, which have not been recomputed. If the  
 283 function finds the pattern ending in entry  $e$ , it stops computing at that point, but

284 to prove correctness it is enough to prove the values are correct in  $M_{\leq e}$ , which  
 285 has been fully recomputed. If, on the other hand, the function does not find the  
 286 pattern, it recomputes the whole structure.

287 We need to show that the values of  $c_v$  and  $c_h$  are always correct for the  
 288 recomputed elements at the end of the function. We proceed by induction on  
 289 diagonals.

290 For the first diagonal it is definitely true since there can only be mapped  $w_1$   
 291 and we check that on lines 7 and 14.

292 When we are recomputing the values of  $c_v(e)$  and  $c_h(e)$  of an element  $e$  in the  
 293 diagonal  $d$ , by induction hypothesis, all elements in diagonals  $d' < d$  are correctly  
 294 recomputed. Let  $cor$  denote the correct value of  $c_v(e)$  as it is defined and  $com$  be  
 295 the computed value. We need to show  $cor = com$ .

296 We can already see  $cor \geq com$  because it holds after setting  $c_v(e)$  on line 5  
 297 and we only increase it, if we manage to find an extension of a mapping, in which  
 298 case there really is a mapping; therefore,  $cor$  is greater or equal to the updated  
 299 value.

300 To prove  $cor \leq com$  we proceed by contradiction. Let us assume  $cor > com$ .  
 301 It means there is a mapping of  $P_{\leq w_{cor}}$  to  $M_{\leq e}$  we have never found. Every such  
 302 mapping has to map  $w_{cor}$  to  $e$ , because if it did not, the mapping would be  
 303 possible even for diagonal  $d - 1$ , which is recomputed correctly and the value  $cor$   
 304 would be copied to  $com$  on line 5. Let us assume that  $w_{cor-1}$  is a vertical entry  
 305 (else we proceed analogously). If  $P_{\leq w_{cor}}$  can be mapped to  $M_{\leq e}$  and  $w_{cor-1}$  is a  
 306 vertical entry, then  $P_{\leq w_{cor-1}}$  can be mapped to  $M_{\leq e_v}$  and  $w_{cor-1}$  must be mapped  
 307 to the same column as  $e$ . That means that  $c_v(e_v) \geq cor - 1$ . If  $c_v(e_v) = cor - 1$   
 308 and from knowing  $w_{cor}$  can be mapped to  $e$ ,  $com \geq c_v(e) \geq c_v(e_v) + 1 = cor$   
 309 because of line 11. Otherwise  $c_v(e_v) > cor - 1$ , but then even from line 5 we get  
 310  $com \geq cor$ , resulting in contradiction.

311 To prove  $c_h(e)$  has the correct value, we proceed symmetrically.

### 312 3.2.4 Generalization

313 The algorithm, with a few minor changes, can be also used for a pattern where all  
 314 one-entries are contained on a walk from the top right corner to the bottom left  
 315 one. The program supports both rotations of a walk and when walking pattern  
 316 is chosen it automatically decides which variant to use.

317 On the other hand, a direct generalization for a general pattern does not work.  
 318 While we can index all entries of the pattern, when trying to map a certain  $w_k$   
 319 to an element  $e$  of  $M$ , it is not sufficient to only check whether  $w_l$  is above and  
 320  $w'_l$  to the left from  $e$ .

321 In Figure 3.3, the entry of  $P$  in the square can be mapped to the element  
 322 of  $M$  in the square and the same holds for entries in the circle but it is not a  
 323 sufficient condition for the entry of  $P$  in the kite to be mapped to the element of  
 324  $M$  in the kite.

$$P = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & \boxed{1} \\ 1 & \textcircled{1} & \diamond 1 \end{pmatrix} \quad M = \begin{pmatrix} 0 & 1 & 1 & 0 \\ 1 & 1 & 1 & 1 \\ 1 & 1 & 0 & \boxed{1} \\ 0 & 1 & \textcircled{1} & \diamond 1 \end{pmatrix}$$

Figure 3.3: The algorithm testing avoidance for walking patterns cannot be easily generalized for all patterns.

## 325 4. Improvements to basic 326 algorithms

327 In this chapter we improve algorithms presented in previous chapters and intro-  
328 duce a parallel method of testing pattern avoidance.

### 329 4.1 General pattern

330 We start by improving the brute force algorithm from Chapter 2.

#### 331 4.1.1 Improving memory consumption

332 The algorithm creates all possible partial mappings and checks whether at least  
333 one can be extended to a full mapping (mapping all lines of the pattern). To  
334 compute all the partial mappings of some level  $l$ , it only uses mappings of level  
335  $l-1$ ; therefore, it is enough to only store partial mappings of two levels in memory  
336 at any time.

337 In Chapter 2 we also introduced the notion of (un)important lines and equiva-  
338 lence based on not using unimportant lines at all (they are fully bounded by other  
339 already mapped lines). When a line becomes unimportant, it stays unimportant  
340 till the end of the test; as a result, we can forget where we mapped those lines to  
341 save memory and only remember where we mapped important lines.

#### 342 4.1.2 Not mapping empty lines

343 **Definition 14.** An *empty* line is a row or a column that does not contain any  
344 one-entries.

345 An empty line can be mapped to any line and we do not need to map it at  
346 all, as long as the algorithm does not map two lines surrounding an empty one  
347 to two consecutive lines.

#### 348 4.1.3 Using the last changed position

349 The MCMC process always changes one element of the big matrix and asks  
350 whether it still avoids the pattern. If it does not and we know that before the  
351 change it did, we are sure the changed element  $[r, c]$  is a part of the pattern. It  
352 is hard to use this fact in the algorithm. It just maps one line after another and  
353 we do not know at the beginning to which line the changed position lines should  
354 be mapped.

355 What we can do is to enforce that neither the  $r$ -th line nor the  $n + c$ -th  
356 one ( $c$ -th column) get skipped. We only look at the restriction for rows as the  
357 restrictions for columns are symmetrical. There are three situations we want to  
358 avoid:

- 359 • The first row of  $P$  is mapped under the  $r$ -th row. This prevents any other  
360 row to be mapped to  $r$ -th one and we do not want that.

- The last row of  $P$  is mapped above the  $r$ -th row. This again prevents any other row to be mapped to  $r$ -th one.
- Two adjacent rows  $l, l + 1$  of  $P$  are mapped to  $L < L'$  respectively and  $L < r < L'$  which leaves no other row to be mapped to  $r$ .

#### 4.1.4 Line order

An important thing, if we want the algorithm to run fast, is to choose a good line order. A line which is unimportant in level  $l$  in a line order may easily be important till the nearly last level in a different order.

We choose line order to hopefully enforce two things:

- Make as many unimportant lines as possible. This really allows the equivalence based improvements to kick in. The more lines are unimportant the more mappings become equivalent and the faster it is to iterate through all of them.
- Recognize hopeless partial mappings as soon as possible. A partial mapping gets extended if the line does not break the rule that there is a one-entry where it needs to be. If we map all the rows first, the rule will get broken only after we start to map columns and we probably want to find out sooner.

In the program a user can either choose their own custom order or one of five algorithms with different main purposes:

- AUTO - this one tries the other three line orders and chooses the one which shows the best performance over some iterations on a matrix. While this may sound like a good thing to use, it is only so if an initial matrix is chosen and it takes a lot of time since a lot of iterations need to be made in order to make a good sample. I would recommend not to use AUTO order at all and instead to try all the line orders by hand with a number of iterations depending on the pattern and a good initial matrix; for instance, generated with a smaller number of iterations on the same pattern and with any line order.
- DESC - the lines are ordered in descending order depending on the number of one-entries. This follows the idea to start with the lines that are the hardest to map. Note that this algorithm does poorly if there are a lot of lines with the same number of one-entries (for example an identity matrix).
- MAX - it orders the lines so that the maximum number of important lines throughout the levels is as small as possible. This focuses straightforwardly to having many unimportant lines, which the program does not remember.
- SUM - it orders the lines so that the sum of the numbers of the important lines is the smallest possible throughout all levels. The purpose is the same as in the MAX order and quite often it is the case both approaches produce the same order.

- TWO - it orders the lines so that the maximum number of important lines in two consecutive levels throughout all the levels is as small as possible. This again focuses to having many unimportant lines, which the program does not remember. The constant two is chosen due to the fact general pattern always stores two levels of partial mapping at a time.

#### 4.1.5 Mapping approaches

The one thing the approaches we will introduce have in common is that they try to recognize those partial mappings that have no chance to be extended to a full mapping as early as possible.

While the algorithm introduced in Chapter 2 finds out the partial mapping is invalid only at the time it maps two lines having a one-entry at their intersection to two lines having a zero-entry at the intersection, different approaches try to reveal the fact we would end up in the situation earlier by checking more conditions. Let  $P$  from Figure 4.1 be the forbidden pattern and imagine a situation,

$$P = \begin{matrix} & \begin{matrix} 5 & 6 & 7 & 8 \end{matrix} \\ \begin{matrix} 0 \\ 1 \\ 2 \\ 3 \\ 4 \end{matrix} & \begin{pmatrix} 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 \\ 1 & 1 & 1 & 0 \end{pmatrix} \end{matrix}$$

Figure 4.1: Pattern  $P$  on which we demonstrate mapping approaches.

in which only lines 0, 3 and 7 are mapped and line 6 is currently being mapped. There are a few necessary conditions we can check:

##### Enough one-entries

The first condition is that there is enough one-entries in between mapped lines, which is schematically shown in Figure 4.2. We check whether there is enough one-entries on lines in between those lines, where lines 0 and 3 are mapped, so that there is a hope we can map lines 1 and 2 there. Similarly, we check whether there is a one-entry below the line, where line 3 is mapped so we can map line 4 there later.

##### Recursive mapping

While we were only testing whether there are enough one-entries in between already mapped lines in the previous approach, as you can see in Figure 4.3, this time we also check whether those one-entries can be used for the lines that are intended to be mapped there. For example, when we check there is a one-entry to be used for line 1 later, we also check the line 1 can be mapped to the row

Figure 4.2: Checking whether there is enough one-entries. Bold lines in the picture are mapped and in circles are the positions where we look for one-entries.

Figure 4.3: Checking whether crossed non-mapped lines can be mapped anywhere. Bold lines are mapped or being mapped, in rectangles are the lines we check and in circles are the positions where we look for one-entries.

430 with one-entry, which in this situation means to also check there is a one-entry  
 431 at the intersection with the line to which the line 7 is mapped.

#### 432 **Orthogonal bounds**

433 As shown in Figure 4.4, when we are adding line 6, we check whether there is  
 434 enough one-entries on the already mapped lines orthogonal to line 6 between line  
 435 6 and the closest mapped lines next to line 6. The idea is same as in “Enough  
 436 one-entries”, but we check different lines.

#### 437 **Usage**

438 These restrictions on the added lines are not a fixed part of the program. A user  
 439 can decide which approaches they want to use in the configuration file.

Figure 4.4: Checking whether there is enough one-entries on the orthogonal lines. Bold lines are mapped or being mapped and in circles are the positions where we look for one-entries.

Pattern	n	#iterations	one	rec	orth	time (sec)	memory
1 0 0	100	100,000	yes	yes	yes	122.24	3,004 B
1 1 1	100	100,000	no	no	no	248.65	3,268 B
0 0 1	500	10,000	yes	yes	yes	1,072.53	5,380 B
	500	10,000	no	no	no	2,631.73	15,976 B
1 1 1	100	100,000	yes	yes	yes	1,512.56	3,268 B
1 1 1	100	100,000	no	no	no	672.63	3,268 B
1 0 0	500	10,000	yes	yes	yes	10,276.60	9,128 B
	500	10,000	no	no	no	6,756.96	15,972 B

Table 4.1: Testing additional restrictions of the generated matrix is useful in some cases but it comes with a performance drop in different cases.

440 When testing that was done for a fixed pattern, we found out it is useful to use  
441 all the mentioned restrictions when generating a matrix avoiding some patterns  
442 while it was much better not to use any of those restrictions for different pattern,  
443 which you can see in Table 4.1. For some patterns it also happened that using  
444 additional restrictions was useful for matrix of size  $100 \times 100$  and for the same  
445 patterns it was better not to use them for generating a  $500 \times 500$  matrix.

#### 446 4.1.6 Using the whole structure in the next iteration

447 It may seem like a good idea to store all the partial mappings. In the next  
448 iteration, instead of finding all the partial mapping again, we only alter the  
449 mappings we remember. Let  $i$  be the number of the iteration we are in, and  $e$  be  
450 the element.

451 If the element  $e$  is changed from zero-entry to one-entry, for each partial  
452 mapping we have stored in previous iterations, we want to try to extend it only  
453 by the line that just changed. If we manage to extend a partial mapping, we  
454 then try to extend it to a full mapping in all possible ways (not only by using  
455 changed lines). When the new line in such a mapping becomes unimportant, we

456 can stop looking for all possible extensions if the mapping is equivalent with a  
457 different one, which comes from previous iterations. This can be easily done by  
458 means already used in the standard algorithm.

459 However, if the element  $e$  gets changed from one-entry to zero-entry we need to  
460 go through the partial mappings and delete all those that use  $e$ . This complicates  
461 the algorithm as we can no longer forget unimportant lines. Moreover, for each  
462 partial mapping we need to remember how many partial mappings of the previous  
463 level can be extended to that one, to delete that mapping from the list if there  
464 are no longer any mappings extensible to it.

465 This can all be done, but it comes with three huge inconveniences:

- 466 • Memory consumption - there can be a lot of partial mappings and we need  
467 to remember them all. We need to remember mappings of all levels and  
468 while we can still use the equivalence when extending a mapping, we need  
469 to also store all equivalent mappings for the purposes of deleting.
- 470 • The change from one-entry to zero-entry is no longer for free. If this change  
471 is done, we already know the pattern is not contained in  $M$ , but we still  
472 need to do a lot of work to change the structure in order to use it in the  
473 next iteration.
- 474 • Reverting - if the change is unsuccessful (the pattern is contained) we need  
475 to revert the change which means to completely revert all changes we did to  
476 the list of partial mappings. This can be either done by making a backup  
477 copy of the whole structure and override the structure if needed, which again  
478 is very costly as the structure is huge, or we can remember what partial  
479 mappings are new (or deleted) and we go through all partial mappings and  
480 remove (add) those. This means to iterate through the big structure one  
481 more time for every unsuccessful change.

482 After realizing these issues it no longer looks useful to me and this version of the  
483 algorithm is not a part of the implementation.

## 484 4.2 MCMC parallelism

485 To speed up computations, it is often possible to use parallelism. In this section,  
486 we show how to make the MCMC generator parallel, while still allowing both  
487 types of the pattern.

488 While the serial MCMC generator in each iteration changes one element in  
489 the generated matrix and checks whether it still avoids forbidden patterns, the  
490 parallel version makes several iterations at once, one on each copy of the generated  
491 matrix. This means that while iteration  $x$  is being computed by a thread, iteration  
492  $x + 1$  can at the same time be computed by a different thread. The issue is that  
493 the iteration  $x + 1$  does not know what is going to be the state of the generated  
494 matrix at the time it should start. It expects iteration  $x$  to fail - not change the  
495 generated matrix at all, counting on the fact, it is unlikely a change does not  
496 create a mapping of the pattern, and starts with the same matrix as iteration  
497  $x$ . If iteration  $x$  succeeds, then the computed iteration  $x + 1$  is invalid and the  
498 iteration is going to be recomputed again, starting with the correct matrix.

499 When the parallel version of MCMC generator is chosen and it is assigned  
500  $n$  threads, it creates  $n - 1$  private copies of the generated matrix and assigns  
501 one thread, called worker, to each of them. The last thread, which we call the  
502 main thread and which has exclusive access to the master copy of the generated  
503 matrix, makes one change of a bit in each private copy of the matrix and makes  
504 the corresponding worker check the avoidance.

505 The job of a worker is only to check if its copy of the matrix still avoids the  
506 pattern when one bit is changed. On the other hand, all synchronization is left to  
507 the main thread. As mentioned before, one iteration of the MCMC process can  
508 be recomputed several times. We still want the generator to satisfy the conditions  
509 we have for the Markov chain (more in Section 1.2) in order to approximate a  
510 random matrix. To achieve that, if a computed iteration  $x$  succeeds (and changes  
511 the generated matrix), all the other computed iterations that would follow after  
512 the iteration  $x$  become invalid and they all have to be recomputed. The process  
513 ends when all iterations get computed.

514 For the sake of clarity, from now on, we will not be talking about iterations  
515 but about tasks. A task is basically one iteration of the MCMC process. The  
516 usefulness of this notation comes with an ID - a number, unique per task, assigned  
517 to each task, starting with 1 and always increasing. For a pair of consecutive  
518 iterations  $x$  and  $x + 1$  it will always be the case that if task  $a$  is the last task  
519 to compute iteration  $x$  (which means the iteration does not get recomputed ever  
520 again after) and task  $b$  is the last task to compute iteration  $x + 1$ , then the ID  
521 of  $a$  is lower than the ID of  $b$ . Also there is no point, in which two different  
522 tasks would be computing the same iteration at the same time. If tasks with IDs  
523  $a < b$  computed the same iteration, it must have been the case an earlier iteration  
524 succeeded when task with ID  $a$  was computed and after it got removed, task with  
525 ID  $b$  was assigned to recompute.

526 At any point in time, we only consider those tasks, that are being computed  
527 or those that wait to be processed (not those that have been processed), which  
528 means the lowest ID of tasks we consider increases in time.

529 When a task ends and it has the lowest ID (we can always wait for the task  
530 with the lowest ID) we do:

- 531 • if it fails:
  - 532 – Do nothing - there is no change to propagate to the master copy of the
  - 533 generated matrix and all the tasks with higher ID expected this task
  - 534 to fail, which it did.
  - 535 – This increases the lowest ID by exactly one, as the task we speak of
  - 536 got processed.
- 537 • if it succeeds:
  - 538 – The main thread propagates the change tested by the task to the
  - 539 master copy of the generated matrix.
  - 540 – All the rest of the task get removed as they all had a higher ID -
  - 541 computed iterations that follow after the one just computed and they
  - 542 expected the task to fail, which it did not.
  - 543 – This increases the lowest ID by more than one, because there are tasks
  - 544 that got removed and one that got processed.

### 545 4.2.1 Example of the MCMC process for $n$ threads

546 At first, iterations 1 to  $n - 1$  are assigned one to each worker as tasks with ID 1 to  
547  $n - 1$  with the same order as the order of iterations. If iteration 1 is not successful  
548 (which all the other iterations count on), everything is alright. However, if the  
549 iteration (its task) is successful, all the results of other tasks (and some of them  
550 might have been already finished) are cleared and those iterations get recomputed  
551 in tasks  $n$  to  $2n - 3$  and the worker that computed task with ID 1 is assigned a  
552 new task with ID  $2n - 2$  - to compute iteration  $n$ . The result of the task gets  
553 propagated to the master copy of the generated matrix only if all the tasks  $n$  to  
554  $2n - 3$  fail, else it gets recomputed. This is what happens till the end.

### 555 4.2.2 Speculative computing

556 It may easily happen that a task not having the lowest ID ends first. In that case,  
557 we could just wait until it has the lowest ID and process it later. This is not a  
558 very efficient approach. Instead we process the task immediately, but we do not  
559 propagate the changes to the master copy of the generated matrix until all tasks  
560 with lower ID fail and we do not stop the workers processing tasks with lower  
561 ID. When a task succeeds we remove all the changes computed by tasks with  
562 higher ID and override their private copy of the generated matrix. Also it might  
563 happen a task with even lower ID succeeds as well. This leads to more and more  
564 overriding. Luckily this is the only precarious situation we may encounter and it  
565 can be dealt with, even without copying the possibly huge generated matrix.

566 The way we deal with these inconveniences is described in Chapter 5 and  
567 should be clear from the code itself.

### 568 4.2.3 Reverting and synchronizing in the main thread

569 The speculative computing discussed above is not the only improvement we can  
570 make. It turns out to be costly to wake a thread to compute a trivial function,  
571 to set a few atomic variables and to fall asleep again. This happens a lot in the  
572 MCMC process. Every time a task succeeds it makes other workers revert the  
573 changes they computed and synchronize the successful change, which are both  
574 trivial functions.

575 To workaround this problem we make a theoretically bad decision, which  
576 comes with very nice practical results. All the reverts and synchronizations are  
577 computed by the main thread instead of by an appropriate worker. There is no  
578 problem with concurrency because the worker is always asleep when a task is to  
579 be assigned and using the fact those tasks are really trivial, it does not make the  
580 rest of threads wait for the main thread for too long while it computes changes.

## 581 4.3 Walking pattern

582 While the brute force implementation of an avoid algorithm for a general pattern  
583 was improved heavily, the algorithm for a walking pattern (see Chapter 3) is very  
584 fast in its nature and cannot be improved. Or can it be?

### 585 4.3.1 Using the last changed position

586 The MCMC process always changes one element  $e$  of the big matrix and asks  
587 whether it still avoids the pattern. If it does not and we know that before the  
588 change it did, we are sure  $e$  is a part of the pattern (a one-entry of the pattern  
589 is mapped to it). Knowing that and using the same inductive proof as we did in  
590 the proof of correctness of the avoid algorithm (see Chapter 2) it is sufficient to  
591 only recompute the part of the inner structure under  $e$  and check if the last entry  
592 of the pattern can be found there.

593 Not only that. We also know, using the fact the structure was completely  
594 correct before the change, that if the values of both  $c_v$  and  $c_h$  of an element did  
595 not change, the element will not cause the element underneath it to change and  
596 we no longer have to recompute other parts of the structure.

597 To use both these facts we replace the cycle through the diagonals by a sim-  
598 ple queue, starting at the position of the last changed element and putting more  
599 positions in if the values of  $c_v$  or  $c_h$  are different than they were before recomput-  
600 ing. The function ends either when the pattern is discovered or when the queue  
601 becomes empty.

### 602 4.3.2 Lazy avoid

603 Lazy avoid is a variant of avoid function used when the MCMC parallelism (more  
604 in Section 4.2) is chosen. While all the other types of patterns have a trivial  
605 implementation of revert function, when using the walking pattern, the inner  
606 structure needs to be modified even when reverting. The MCMC parallelism  
607 turned out to work much better if the revert calls are handled by the main thread  
608 and it requires the function to run as fast as possible so the other threads are not  
609 blocked by the call for too long. That is a reason why functions lazy revert and  
610 lazy avoid were created.

611 The avoid function expects the inner structure of the walking pattern to be  
612 in a valid state and that requires some effort. To make lazy revert the fastest  
613 possible, we postpone the work until the next call of lazy avoid, meaning that  
614 lazy avoid then needs to do more things at once. It is no longer sufficient to only  
615 compute the submatrix under the position changed last as we did above, but it  
616 needs to also compute changes in the positions changed in those lazy revert calls  
617 that are postponed.

618 We discuss several approaches, starting with the simplest one and ending with  
619 the one that is fast and used in the final implementation.

### 620 Recompute the whole structure every time

621 The easiest way to implement lazy avoid is to always recompute the whole inner  
622 structure. In that case, we do not worry which positions are correct and which  
623 are not, because every time we find the pattern, we recomputed all the entries  
624 that form it, so we know it really is there.

625 The weakness is efficiency. If the whole structure was correct and there was a  
626 change of the last entry of the matrix it is sufficient to only recompute that one  
627 entry. Instead we recompute a possibly very big structure. This results in a very  
628 bad performance negating the advantage of parallel computation.

## 629 **Recompute only a part of the structure diagonal by diagonal**

630 A simple improvement is to remember the changes done in previous calls of lazy  
631 revert and together with the change done in lazy avoid call only recompute the  
632 part of the structure that has possibly changed.

633 This gets more complicated when lazy avoid call discovers the pattern in  $M_{\leq e}$ ,  
634 because we cannot be sure the rest of the structure (everything under the diagonal,  
635 where  $e$  is present) is in a correct order. It is still possible to remember some  
636 horizontal, vertical and diagonal bounds and use them to restrict the recomputed  
637 part of the matrix. However, the improvement is not that significant and we can  
638 do better.

## 639 **Queue of positions to recompute**

640 A different approach is closer to the one used in a standard avoid function. Instead  
641 of going through diagonals one after another, we have a queue of entries-to-  
642 recompute. It is no longer sufficient to have a standard queue since in different  
643 calls of lazy revert/avoid we can possibly change an entry of different priority  
644 (the smaller diagonal the more important) so we need to have some kind of a  
645 priority queue. That is exactly what I tried.

646 Using `std::priority_queue`, the function has no more problems with recomput-  
647 ing the entries that were not influenced by the changes and uses all the benefits  
648 mentioned in the previous section. But the container does not come for free and  
649 in the end it turns out the price we pay for the operations on the priority queue  
650 make the whole implementation comparably slow as in the previous attempts.

## 651 **Two leveled queue of positions to recompute**

652 The final solution comes with the same idea, but a different storage. As the prior-  
653 ity depends upon a diagonal (two entries on the same diagonal can be recomputed  
654 in any order) we only remember a priority queue of diagonals and an array of  
655 diagonals saying whether a diagonal is already a member of the priority queue.  
656 As far as the entries are concerned, for every diagonal we have a `std::vector` of  
657 entries-to-recompute as well as an array saying whether an entry is already a  
658 member of the vector. Finally, it is the case that the storage used is not only  
659 good theoretically but as the numbers say, also practically.

## 660 **4.4 Comparison of all methods**

661 We have improved all algorithms and added a parallel version of the MCMC  
662 process. The question is, whether our improvements were useful in terms of  
663 performance and memory consuming. I have done a few tests and in Table 4.2,  
664 Table 4.3 and Table 4.4, you can see that at least in some cases walking pattern  
665 does much better than general pattern and that parallel computation was not  
666 added without a good reason. We always generate a matrix of size  $n \times n$  and if  
667 there is one thread, we use the serial variant of MCMC process; otherwise, we  
668 use the parallel one.

Pattern	n	#iterations	type	threads	time (sec)	memory
1 1 1	100	100,000	general	1	1,486.61	< 100 KB
1 1 1	100	100,000	general	9	381.56	602 MB
1 0 0	100	100,000	general	17	332.46	1,173 MB

Table 4.2: A table showing the difference between using parallel and serial MCMC process.

Pattern	$n$	#iter	type	#th	time (sec)	memory
0 0 0 0 1	100	100,000	general	1	3187.17	3.9 MB
0 0 0 1 0	100	100,000	general	9	569.23	24.3 MB
0 0 1 0 0	100	100,000	general	17	336.78	39.9 MB
0 1 0 0 0	100	100,000	walking	1	5.31	2.9 MB
1 0 0 0 0	100	100,000	walking	9	2.06	4.2 MB
	100	100,000	walking	17	1.91	5.1 MB

Table 4.3: A table comparing general and walking pattern performance on the same pattern.

Pattern	$n$	#iterations	type	#th	time (sec)	memory
$I_{10}$	100	100,000	general	1	1,486.61	< 100 KB
	100	100,000	general	9	381.56	602 MB
	100	100,000	general	17	332.46	1,173 MB
	500	100,000	walking	1	137.74	19 KB
	500	100,000	walking	9	38.85	614 MB
	500	100,000	walking	17	31.41	1,210 MB
	5,000	10,000	walking	1	3,588.79	467 MB
	5,000	10,000	walking	9	1,105.49	5,025 MB
	5,000	10,000	walking	17	685.04	9,174 MB

Table 4.4: A table comparing general pattern and walking pattern, as well as usage of parallel version of MCMC process.

## 669 5. Technical documentation

670 In this chapter, we cover those parts of the algorithm that may be hard to un-  
671 derstand just from the code. This only means functions that are technically  
672 hard, for example functions with unexpected dependencies, side effects and so  
673 on. Algorithmic difficult tasks are explained in Chapter 4.

### 674 5.1 Classes and API

675 First we list important classes of the program and explain their purpose.

#### 676 5.1.1 Matrix

677 A minimalistic template container for storing and accessing matrices.

#### 678 5.1.2 Pattern

679 An abstract class defining the interface of patterns. Three classes inherit from  
680 the class:

- 681 • *General\_pattern* – more in Chapter 2
- 682 • *Walking\_pattern* – more in Chapter 3
- 683 • *Slow\_pattern* – a class using a brute force algorithm to test pattern avoid-  
684 ance.

685 For the case multiple patterns are chosen at the same time, every such Pattern  
686 is stored in a container called Patterns, which is a class creating an interface  
687 between Pattern and MCMCgenerator.

#### 688 5.1.3 Statistics

689 To acquire, store and output statistics of the generating process, we use classes  
690 in the file Statistics.hpp. There are two kinds of classes:

- 691 • *Matrix statistics* – these statistics store information about the structure of  
692 all matrices that have been generated throughout the MCMC process. An  
693 example of that is a histogram of occurrences of one-entries at all positions  
694 of the matrix.
- 695 • *Performance statistics* – this is what we use to count how many changes  
696 were successful and how long did it take to test a change.

697 If user wants to define their own statistics, they can add variables into the  
698 class, alter “add\_data” function to allow storing the desired data and change  
699 function “print...” to define the output.

## 700 5.2 General\_pattern

701 The general pattern class contains a lot of function. Most of them are easy to  
702 follow and they all should be commented enough in the code. The only part  
703 which deserves more attention is the constructor.

### 704 5.2.1 Construction

705 In the constructor of a general pattern, there are a few function that are easy in  
706 nature but as they somehow use each other it is hard not to lose track of their  
707 dependencies and results. In order to make this part of the code, which is very  
708 important, more understandable, we go through the constructor and explain all  
709 that is happening in the order it is happening in.

#### 710 Storing the pattern

711 The first thing, which is done right after initialization of variables, is storing the  
712 pattern. Instead of storing the pattern in a `Matrix<bool>`, I decided to store  
713 lines into a number, where in the binary coding a one-entry in the position  $i$   
714 means there is a one-entry in the line at the intersection with  $i$ -th orthogonal  
715 line. This comes handy when computing line orders. At the same time we also  
716 find those lines that are empty (more in Chapter 4) and remember them, because  
717 we do not have to map them at all.

#### 718 Choosing the line order

719 After that, we need to choose the right line order (again more in Chapter 4).  
720 To compute MAX, SUM or TWO order we use a brute force algorithm that  
721 checks sequences of line adding and for each it computes how many lines are  
722 unimportant. Then it just chooses the order which is the best in chosen metric.  
723 To compute DESC order, we sort the lines according to the number of one-entries.

#### 724 What to remember

725 In the next step, we find which lines are important in each level of partial map-  
726 pings with respect to chosen order, because what to remember is based on the  
727 equivalence introduced in Chapter 2 and the decision not to remember unimpor-  
728 tant lines, which we explained in Chapter 4.

#### 729 Parallel bound indices

730 Now comes the hardest to follow part – precomputing the indices for searching  
731 for parallel bounds. The idea is simple. When we are adding a new line and we  
732 already have a partial mapping, it restricts to where we can add the line. For  
733 example, if there are three rows in the pattern and the rows 1 and 3 are mapped,  
734 then line 2 needs to be mapped in between those two. The question is, where are  
735 those two lines mapped to?

736 First, we add in a chosen order and second we do not remember all lines, as  
737 some are unimportant. What do we want is to have an instant access to indices  
738 of lines, which bounds added line in the partial mapping, so we do not need to

739 compute the index over and over again. That is exactly what gets computed when  
740 the function “find\_parallel\_bound\_indices” is called. The series of other function  
741 calls follows just because we compute the indices for all added lines in the order  
742 in which they are going to be added.

### 743 **Extending order**

744 The last function, “find\_extending\_order” specifies how we store an extended  
745 partial mapping. Again, unimportant lines play their role here and it may easily  
746 be the case from a partial mapping storing  $k$  lines, after mapping one more  
747 line, we end up with a partial mapping only storing  $k - 1$  lines, because two  
748 lines become unimportant by adding the line. This means we not only copy the  
749 previous mapping and add the new mapped line but also remove unimportant  
750 lines. This function precomputes which values are going to be copied and which  
751 are going to be skipped.

## 752 **5.3 MCMC parallelism**

753 While the idea behind MCMC parallelism is described in Section 4.2 and the  
754 code is heavily commented, the work done by the main thread may still be hard  
755 to understand.

756 Let  $I$  be the ID the process is currently waiting for, that is, the lowest ID of  
757 a task that is being tested by a worker. In a structure called “queue” (which is  
758 `std::vector<std::deque>`) each worker has a queue of tasks assigned to it. In the  
759 queue, there are tasks that are either being computed or have been computed.  
760 The history of tasks is needed to allow reverting changes that should have not  
761 happen when the main thread encounters a different successful task with lower  
762 ID. There is no need to have a complete history of all tasks computed. There  
763 are only those tasks, that have higher ID than  $I$  or have lower ID, but those are  
764 going to be removed from the “queue” as soon as possible. The name “queue” is  
765 not random, it describes the order, in which the tasks are being stored – the tasks  
766 with lower ID have been inserted earlier and therefore they are at the bottom.

767 Now that we know the most important structure let us see how the main  
768 thread works with it. This is a list of operations changing “queue” and the  
769 situations, in which we perform them:

- 770 • `pop_front`: The main thread deletes the first task (the one with the lowest  
771 ID) if one of two things happen:
  - 772 – The ID of the task being deleted is equal to  $I$ . That means the change  
773 computed by the task is being propagated to the generated matrix and  
774 there is no need to remember the task anymore. This also increases  $I$ ,  
775 not necessarily by one.
  - 776 – The ID of the task being deleted is less than  $I$ . This situation happens  
777 due to synchronization. The worker was supposed to synchronize a  
778 task computed by a different worker that did not have the lowest ID  
779 at the time. Therefore, the task needs to be in the list of tasks so we  
780 can revert it later, if needed. If there is no need to revert it and the

lowest ID gets greater or equal to the ID of the task, we can just delete it from the “queue”.

- `pop_back`: There is only one reason to delete tasks from the end of the “queue” and that is reverting. Imagine there is a task with id  $J$  at the end of the “queue”. A different worker computes a task with lower ID and finds out the change is successful. This means the task  $J$  will not propagate to the generated matrix and there is no use for it. If it is still being computed, we cannot do much about it, so we tell the worker to stop computing and deal with it later. If the task is finished, we need to revert it, but only in case the task was successful, because if it was not, it had already been reverted by the worker. So we revert the task if needed and we can just delete it from “queue” as it will never be used.
- `emplace_back`: The main thread only inserts new tasks to the end of the “queue” and there are two reasons to insert:
  - Worker is assigned a completely new task to check the avoidance. In this situation, the task is given a new, globally highest ID and we add the task at the end of the “queue”.
  - The second reason to insert into “queue” are synchronizations. The situation is the same as it was in the case, when we `pop_back` – after we revert all the tasks in the list, we need to synchronize changes that forced reverting and if their ID is not lower or equal to  $I$ , we need to add them to the list so they can be reverted if needed.

## 803 6. User documentation

804 In the last chapter of the thesis, we first describe how to install the program and  
805 then show how to make the program generate random matrices or to test whether  
806 a certain matrix avoids a given forbidden pattern.

### 807 6.1 Installation

808 The program is written in C++ and should be compilable on any standard plat-  
809 form. To use it, you either just use an executable file (Windows) or build the  
810 program using C++ compiler.

#### 811 6.1.1 Windows

812 Windows users can run the application using an executable file “matrix-win.exe”  
813 either directly, in which case the default configuration file will be used, or using  
814 command line with an optional parameter specifying the configuration file.

#### 815 6.1.2 Unix, Linux, MacOS

816 Users on other platforms than Windows can build the solution using command  
817 line easily by running “./build.sh”, which uses G++ compiler. Compiler can be  
818 switched by rewriting g++ to some other variant (for example clang) in build.sh  
819 file. This leads to creating a an executable file “matrix.exe” which can be run  
820 with an optional parameter specifying the configuration file.

## 821 6.2 Configuration file

822 In order to modify what the program computes, we use a configuration file. The  
823 configuration file can be chosen when running the program in command line  
824 and relative path to it is the first (and only) option. If no path is inserted, the  
825 configuration file is expected to be located in the same directory as the executable  
826 file and its name is “config.txt”.

827 The file is a standard text file, which can be modified by any text editor, and  
828 is structured into four sections:

- 829 • input
- 830 • pattern
- 831 • output
- 832 • statistics

833 The order of the sections is not fixed and there can be additional empty lines for  
834 better readability. In each section, there is a list of values that can be set either  
835 to arbitrary value or to a specific one. There is at most one command of format

836 “option=value” per line and there might be additional white spaces surrounding  
837 the “=” sign.

838 If an option is set more than once, the latter value is always used. If, on the  
839 other hand, an option is not set at all, the default value is used. If there is a  
840 line encountered that sets a wrong option, for instance when the user mistypes a  
841 valid option, the line is skipped and the user gets a warning in the standard error  
842 output.

843 Let us provide a list of all options for each section together with their default  
844 values.

### 845 6.2.1 Input

846 In the first section of the configuration file, we set the generating process.

- 847 • size: The size of the generated matrix. Results in  $M \in \{0, 1\}^{size \times size}$ .

Possible value:  $s \in \mathbb{N}$   
848 Default value: 100

- 849 • iterations: The number of iterations of the MCMC process.

Possible value:  $i \in \mathbb{N}$   
850 -1 - tests avoidance of the initial pattern  
Default value: 10,000

- 851 • random\_seed: The random seed for the MCMC process.

Possible value:  $s \in \mathbb{N}$   
852 “random” - chooses a random seed  
Default value: “random”

- 853 • init\_matrix: A  $size \times size$  matrix the MCMC process starts with.

Possible value: *matrix file path*  
854 “zero” - a matrix containing no one-entries  
Default value: “zero”

- 855 • parallel\_mode: A choice to compute in parallel or serial.

Possible value: “serial”  
856 “mcmc” - more in Section 4.2  
Default value: “serial”

- 857 • threads\_count: The number of threads used if a parallel mode is chosen.

Possible value:  $t \in \mathbb{N}$   
858 -1 - chosen according to the number of cores  
Default value: 1

### 859 6.2.2 Pattern

860 In this section, we set the options that matter the most – matrix patterns. As  
861 we are allowed to generate a matrix which avoids more than just one pattern,  
862 the section [pattern] can be used multiple times, specifying one pattern for each  
863 occurrence.

864     • `pattern_file`: A relative path to a input matrix file - the pattern.  
           Possible value: *matrix file path*  
 865           Default value: “pattern/input.txt”

866     • `pattern_type`: The type of the pattern. Determines the method used for  
 867       testing avoidance.  
           Possible value: “general”  
                           “walking” - see Chapter 3  
 868                           “slow” - brute force algorithm for a general pattern  
           Default value: “general”

869     The next options are only useful if the general pattern type is chosen. It  
 870     specifies how the mappings are stored as well as what the map function tests.  
 871     First we can decide what mapping approaches to use. More about them in  
 872     Section 4.1.5.

873     • `map_one_entries`: If set to “yes”, the map function tests whether there is  
 874       enough one-entries in between already mapped lines.  
           Possible value: “yes”  
                           “no”  
 875           Default value: “yes”

876     • `map_recursion`: If set to “yes” and the `map_one_entries` is also set to “yes”,  
 877       the map function tests mapping recursively.  
           Possible value: “yes”  
                           “no”  
 878           Default value: “yes”

879     • `map_orthogonal_bounds`: If set to “yes”, the map function also tests the  
 880       orthogonal bounds of added line.  
           Possible value: “yes”  
                           “no”  
 881           Default value: “no”

882     • `map_container`: A container in which the partial mappings are stored.  
           Possible value: “set” - `std::set` (red-black tree)  
                           “hash” - `std::unordered_set` (hash table)  
 883                           “vector” - `std::vector` (dynamic array)  
           Default value: “hash”

884     • `line_order`: Chooses the order in which the lines are being added to the  
 885       partial mapping. See Section 4.1.4.  
           Possible value: “max”  
                           “two”  
                           “sum”  
                           “desc”  
 886                           “auto”  
                           *order file path*  
           Default value: “max”

### 887 6.2.3 Output

888 In this section, we specify, where to output the generated matrix or statistics  
889 files. As the matrix can be output to console, a text file or a bmp file, each  
890 option in the section can be set more than once and every occurrence will make  
891 a new output.

- 892 • `matrix_output`: The generated matrix can be output as a bmp file in which  
893 one-entries are black pixels and zero-entries white. To do that, the file path  
894 has to have a pattern `*.bmp`. If a different path is given the file is stored  
895 as a matrix text file. It can also be output into a console if `“console”` is set.  
896 In that case it has the text format.

Possible value: `“console”`  
matrix bmp file path  
897 matrix text file path  
`“no”`

Default value: `“no”`

- 898 • `performance_stats`: If the serial computation is chosen, the program can  
899 output a statistics like the percentage of avoid call success, how long did  
900 one call take on average and what was the average size of structures. If more  
901 patterns are chosen at the same time, the statistics may get misleading as  
902 they also count the cases when the first pattern is contained in the matrix  
903 and the other patterns are not tested at all.

Possible value: `“console”`  
performance file path  
904 `“no”`

Default value: `“no”`

- 905 • `performance_csv_stats`: The same information as above but formatted to a  
906 csv file so the data can be more easily worked with.

Possible value: `“console”`  
csv file path  
907 `“no”`

Default value: `“no”`

- 908 • `time_to_console`: Prints how long the computation took into a console.

Possible value: `“yes”`  
909 `“no”`

Default value: `“no”`

- 910 • `patterns_to_console`: Prints all the used patterns into the console.

Possible value: `“yes”`  
911 `“no”`

Default value: `“no”`

### 912 6.2.4 Statistics

913 The last section handles the options important for scientists. While generating  
914 a random matrix is a great result, on its way the program can also create some

915 statistics, namely make a histogram of occurrences of one-entries in a generated  
 916 matrix as the MCMC iterates as well as store the matrix with the highest amount  
 917 of one-entries. As the process usually does not start with a random matrix, the  
 918 user can decide to only compute the statistics after a certain number of iterations  
 919 has been done and to only check a small portion of iterations, every 10th for  
 920 instance, as a single iteration may not make any difference and counting the  
 921 histogram takes time.

- 922     • `histogram.frequency`: Sets how often the histogram gets refreshed.  
           Possible value:  $f \in \mathbb{N}$   
                             0 - the histogram is not computed at all  
           Default value: 0
- 924     • `histogram.initial`: Sets the initial iteration of the MCMC process when the  
           histogram gets refreshed.  
           Possible value:  $i \in \mathbb{N}$   
           Default value: 1,000
- 927     • `histogram.final`: Sets the last iteration of the MCMC process when the  
           histogram gets refreshed.  
           Possible value:  $f \in \mathbb{N}$   
                             -1 - the histogram is computed till the end  
           Default value: -1
- 930     • `histogram.file`: Sets where to output the histogram computed during the  
           MCMC process.  
           Possible value: matrix bmp file path  
                             matrix text file path  
                             "console"  
                             "no"  
           Default value: "no"
- 933     • `max_ones_matrix.file`: Sets where to output the matrix that had the most  
           one-entries among all matrices iterated through during the MCMC process.  
           Possible value: matrix bmp file path  
                             matrix text file path  
                             "console"  
                             "no"  
           Default value: "no"

## 936 6.3 File input

937 There are only two types of input files expected by the program. Either you want  
 938 to read a matrix file, which can be a pattern or an initial matrix, or an order file  
 939 that determines an order in which the lines are going to be mapped if the general  
 940 pattern is chosen.

### 941 6.3.1 Matrix file

942 A matrix file is a standard text file having the format as follows:

- 943 • 2 natural numbers specifying the number of rows and columns in this order.
- 944 • a sequence of zeros and ones of length rows×columns specifying the matrix
- 945 from the top left corner one row after another.

946 **Example:**        2 3  
                     1 0 1  
                     1 1 0

### 947 6.3.2 Order file

948 If you want to choose the order in which the lines are going to be mapped when  
949 a general pattern is chosen, it is your responsibility to check that all lines that  
950 need to be mapped are mapped. It is for example possible to only map three lines  
951 even if the pattern consists of six lines just because there is for example no need  
952 to map empty lines at all. Therefore the program does not check the validity of  
953 the order and just uses it.

954 Now that the user has been warned, the format of the custom order file is  
955 simple. It consist of the indices of the lines of the pattern numbered starting  
956 with 0 and starting from the top row and ending with the right column.

957 One possible order for the matrix given as an example in [6.2.1] is this file:

958                                2 1 0 3 4

959 First mapping the left column, the second and first row after that and finishing  
960 the mapping with the middle column and the right one.

## 961 6.4 File output

962 Let us now find out what the output files look like.

### 963 6.4.1 Matrix text file

964 The matrix text file has the same format as the input one. It consists of:

- 965 • 2 natural numbers specifying the number of rows and columns in this order.
- 966 • a sequence of zeros and ones of length rows×columns specifying the matrix
- 967 from the top left corner one row after another.

968 The matrix is binary except for the one produced as a histogram, which can have  
969 higher natural numbers and contains the number of samples as the last number.  
970 If you then divide all the entries by the last number, you get a percentage of the  
971 entry being a one-entry.

## 972 **6.4.2 Matrix bmp file**

973 For an  $n \times n$  matrix the standard bmp file contains  $n \times n$  pixel of black color  
974 meaning a one-entry and a white color for a zero-entry. If the histogram is output  
975 as a bmp file, the pixels are greyscaled and the darker a pixel is the more often  
976 the entry was a one-entry during the MCMC process.

# Conclusion

We have seen, how to use Markov chain Monte Carlo method to approximate a random matrix of given size avoiding a given set of forbidden patterns. We have used a heavily improved brute force algorithm to test avoidance of a general pattern and a simple dynamic programming algorithm for testing avoidance of a pattern, where all one-entries are contained on a walk in the pattern. To even more improve performance of the program, we have used parallel computing in the layer of the MCMC process.

The question is, whether we can do better? We probably cannot asymptotically improve the walking pattern avoidance algorithm (more in Chapter 3), because it is already linear in the number of elements of the matrix and computes only those elements that have changed. On the other hand, the algorithm is only useful for a small portion of all possible patterns. A natural question is, whether we can do as good for other classes of matrices?

In Section 4.1.6, we mentioned an alternative algorithm for testing avoidance of general patterns. Although it is probably not a very good algorithm for big matrices, because it needs to store all possible partial mappings, it may still turn out to be much better for smaller matrices, which are still big enough to see a structure in them, than the implemented algorithm is.

To use parallelism, we decided to use the MCMC layer of the program. There were several reasons to do so. First of all, it is not dependent on the avoidance pattern algorithm; therefore, if someone comes with a better one, it can still use the parallel version of MCMC. Secondly, when the matrix gets complex enough, the probability a change of one element is going to be successful is very small; thus, we have chosen to iterate through unsuccessful changes faster over the possibility to test avoidance faster.

A different approach would be to make avoidance testing parallel. In walking pattern, we could recompute multiple elements of the same diagonal at once, because they do not influence each other. In the algorithm for general patterns, we could generate new partial mappings in parallel, since they are independent. The only problem there is deciding whether two mappings are equivalent.
